Even-aged to uneven-aged

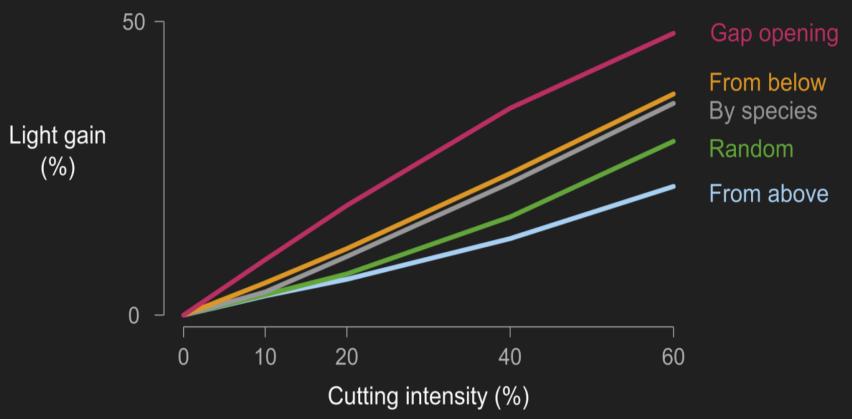

- Coniferous plantations (monoculture), still cover large areas in Europe
 - 50% of forest areas in Belgium
 - Traditionnally, these stands are managed with clear-cuts and plantations
- Silviculture avoiding clear-cutting is more and more encouraged or even imposed by regulation
 - Pro-Silva silviculture must be applied in state-owned forest in Belgium
 - Clear-cuts are forbidden in peri-urban forests around Paris, France
 - **–** ...
- But very few guides for practionners...
 - How long does it take to reach an equilibrium state and to harvest the planted trees?
 - What is the forest productivity during the transformation period?
 - What will be the composition (and resilience) of future uneven-aged stands?

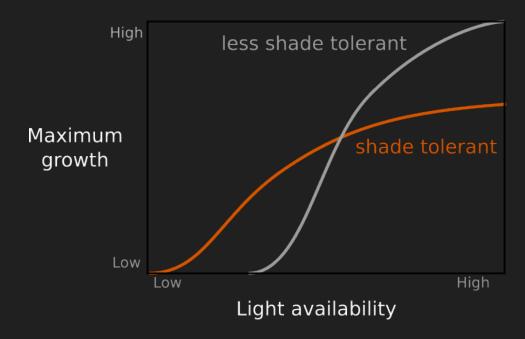

Assumed to be a limiting factor under continuous cover forestry

- Assumed to be a limiting factor under continuous cover forestry
- Understory light levels can be controlled by partial cuttings

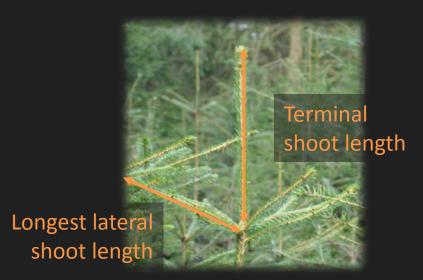

- A limiting factor under continuous cover forestry
- Understory light levels can be controlled by partial cuttings
- Drive inter-specific competition

- A limiting factor under continuous cover forestry
- Understory light levels can be controlled by partial cuttings
- Drive inter-specific competition
- The apical dominance ratio has been suggested to be a good indicator of understory light conditions for some species

 $ADR = \frac{terminal\ shoot\ length}{Longest\ lateral\ shoot\ length}$

Research questions

- Can we expect that tree species diversity will increase in stands managed without clear-cut? What are the light conditions that best promote species diversity? Can we control it?
- Is the Apical Dominance Ratio (ADR) a good indicator of understory light for that purpose?

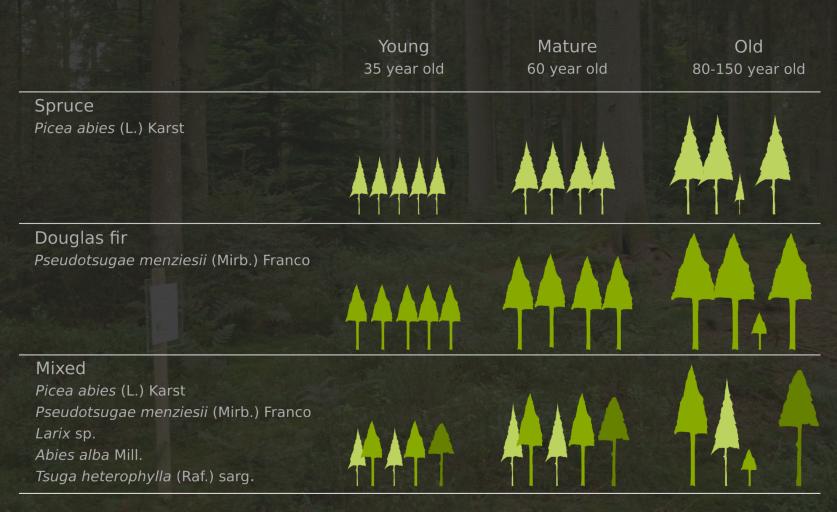

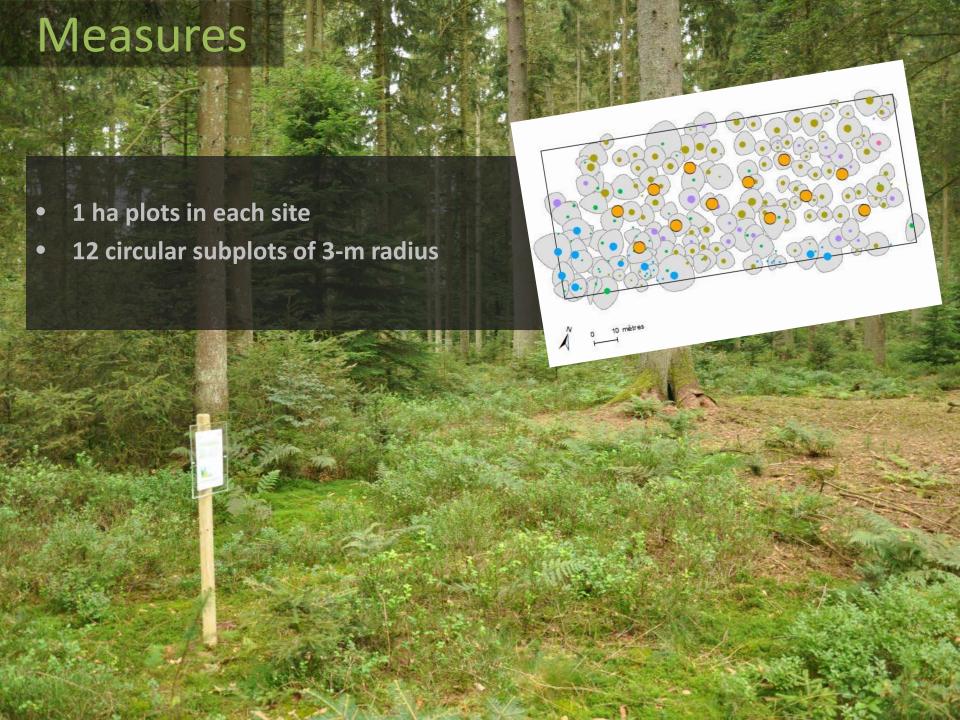

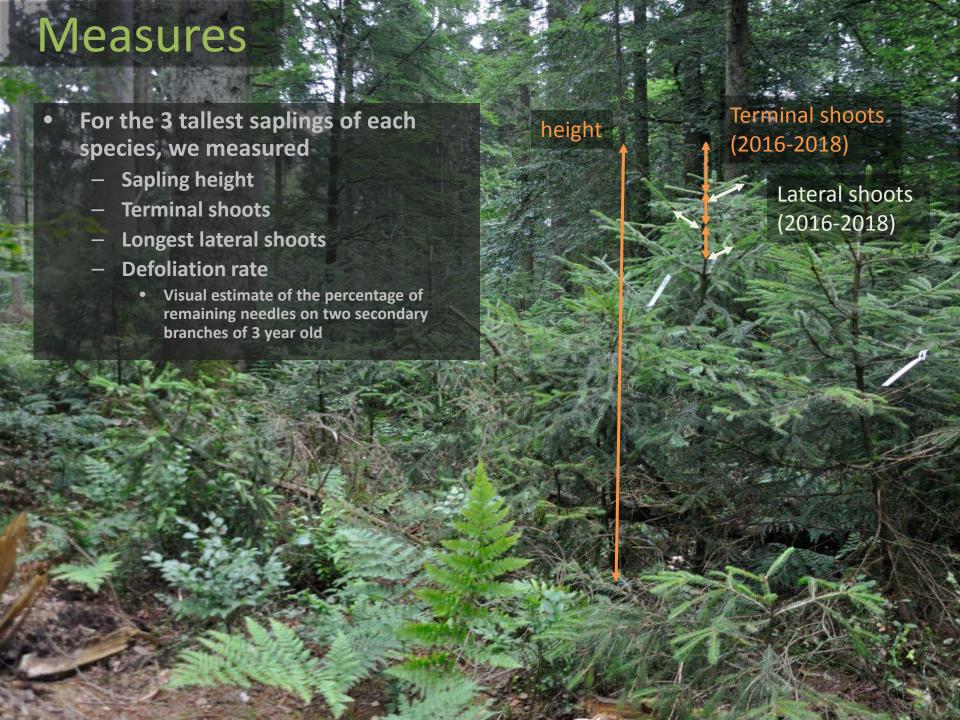

Study area

9 coniferous stands in Belgium at 400-600 m a.s.l

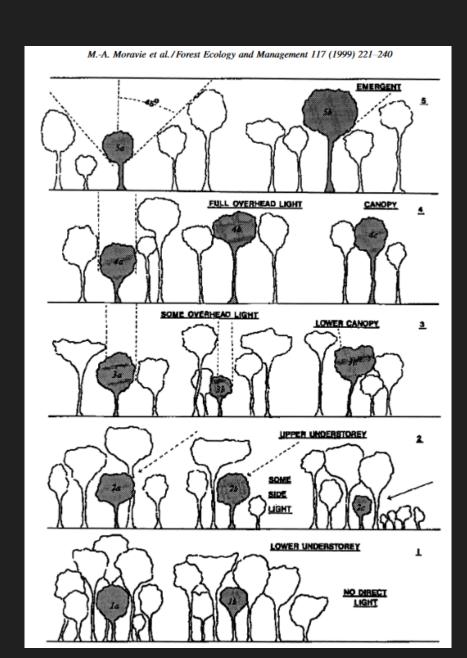

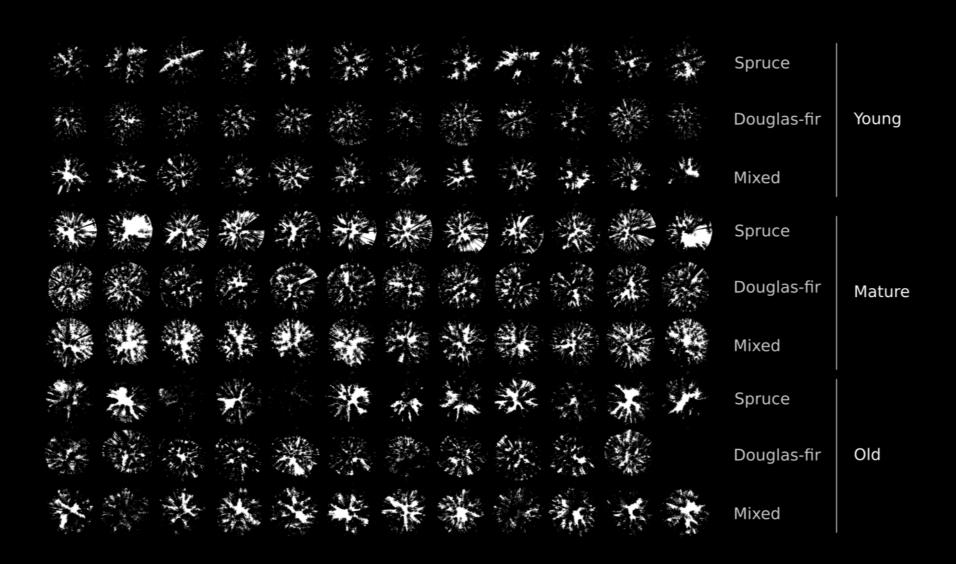

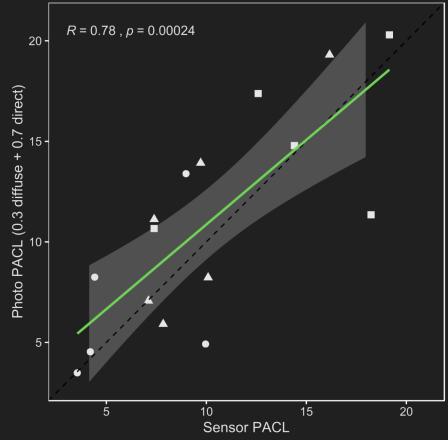

Measures

- For the 3 tallest saplings of each species, we measured
 - Sapling height
 - Terminal shoots
 - Longest lateral shoots
 - Defoliation rate
 - Visual estimate of the percentage of remaining needles on two secondary branches of 3 year old
 - Competition index
 - Dawkins classification

In spring 2018, 107 hemispherical photographs to measure to percentage of above canopy light (PACL), taken above the regeneration of each subplot (with a telescopic pole and an auto-stabilized device)

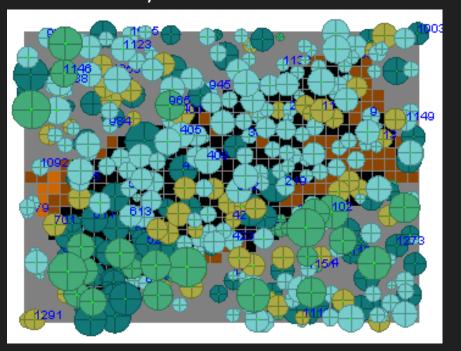

Validation of photo thresholiding measuring understory light with light sensors during two days in three study sites

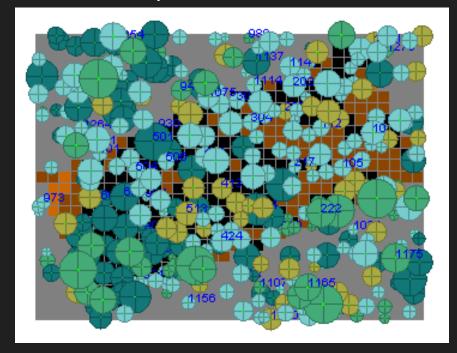

Simulations with **SamsaraLightLoader** (Capsis4) to estimate the understory light before 2018 to take into account tree mortality and thinnings

Tree inventory of 2016

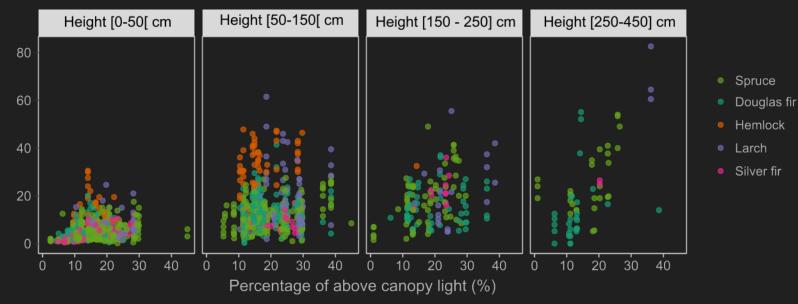

Tree inventory of 2018

Summary statistics

- n = 1354 measures of terminal shoots of 565 saplings
 - 247 spruces
 - 141 douglas firs
 - 56 larches
 - 58 silver firs
 - 54 hemlocks
- Height up to 445 cm
- PACL varying from 1% to 45%

Modelling terminal shoot lenght

Non-linear mixed model fitted with the restricted maximum of likelihood

```
terminal shoot length i_{i,j,k,l} = (a + \alpha_i) height ^b_{i,j,k,l} PACL ^c_{i,j,k} + \varepsilon_{i,j,k,l}
```

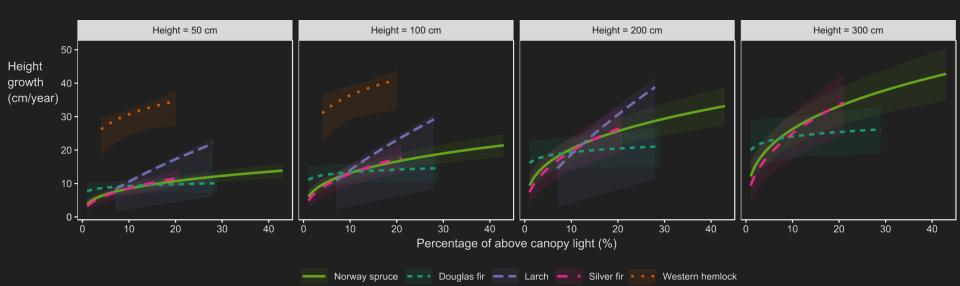

with *a, b, c* the fixed parameters

 α a random plot effect : $\alpha \sim N(0, \sigma_a)$

 ε the random residual error : $\varepsilon \sim N(0, \sigma_{\varepsilon})$

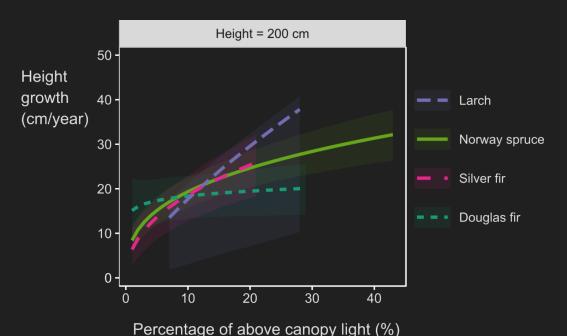

Modelling terminal shoot lenght

- Terminal shoot logically increased with height and PACL
- Western hemlock, a very shade tolerant species, had terminal shoot about three times that of the other species in all observed light conditions (no saplings of height ≥ 200 cm observed)

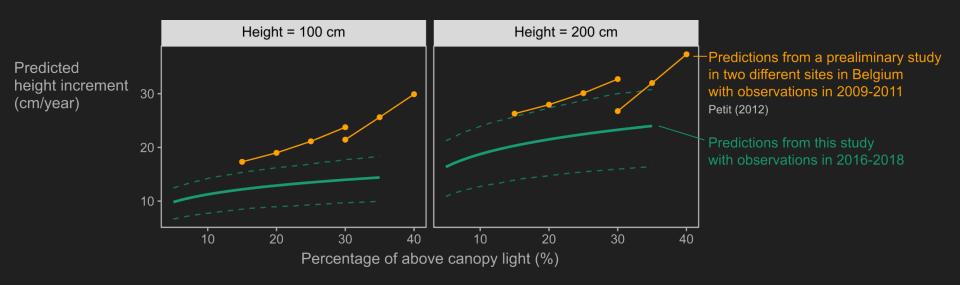

Modeling terminal shoot lenght

- Not considering Western Hemlock:
 - In low light conditions, all species grow at relatively similar height growth rates
 - In high light conditions, some species can grow faster than others. They are by order of decreasing height increment:
 - 1. Larch (shade intolerant)
 - 2. Spruce (shade tolerant)
 - 3. Silver fir (very shade tolerant)
 - 4. Douglas fir (less shade tolerant)

What's wrong with the Douglas fir?

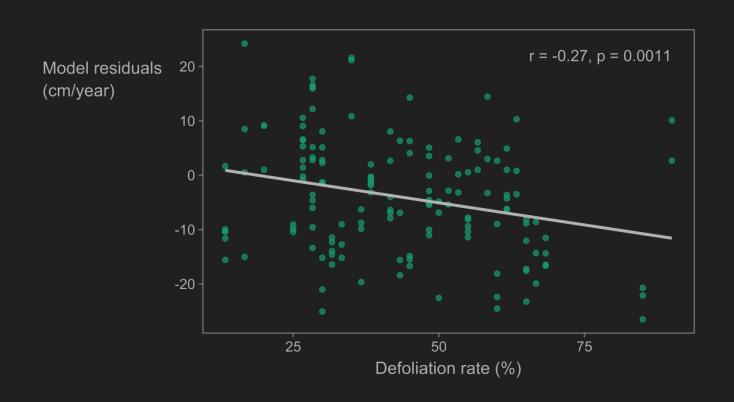

We expected larger height increment and stronger response to light

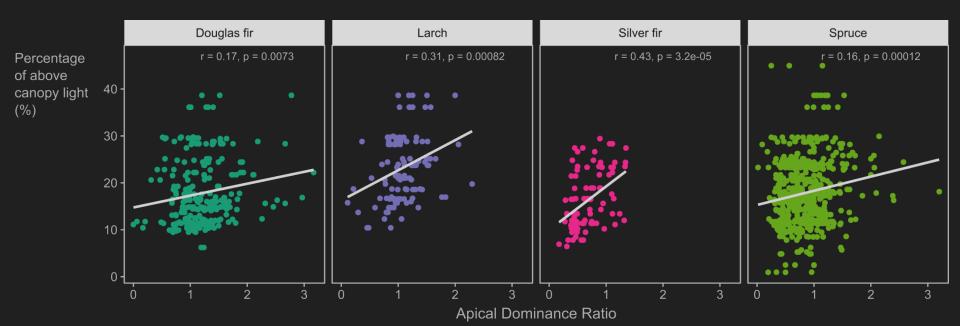

Defoliation rate and douglas fir growth

- In average, douglas fir saplings had a defoliation rate of 50% while silver fir and spruce had a defoliation rate of about 20%.
- We found a weak but significant correlation between the residuals of the height increment model for douglas fir and the defoliation rate

ADR: a good indicator of understory light?

- For all species but Western Hemlock, the relationships between ADR and PACL are significant but weak: R² < 19%
- PACL estimate at subplot center may not be accurate enough to estimate the light transmitted to the saplings (sometimes 3m away from the subplot center)
- Other factors likely interacts (e.g. pathogens)
- Picking one sapling at random and estimating its ADR, will likely not provide accurate measure of understory light (within the studied range of light conditions (1-40%))

Is the conversion from even-aged to unevenaged an opportunity to increase future stand diversity?

 Hemlock regeneration generally outcompeted other tree species. This thread can likely not be avoided by controlling understory light (whithin the range of light conditions observed with continuous cover forestry).

 Natural regeneration of Douglas fir in Belgium suffers from different pest and pathogens which likely reduce its competitivity and future abundance.

 Maintaining closed canopies can be used to reduce the vigor of the most vigorous species and increases the probability of less vigorous species to be recruited.

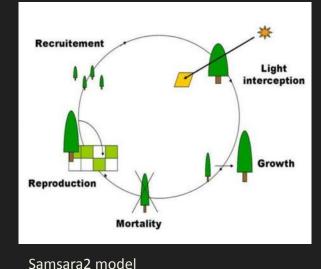

Perspectives

 Implement these models in a forest dynamics simulator to simulate the conversion of even-aged to uneven-aged structure and provide silvicultural guides

and in particular sapling and young tree

survival

Continue evaluating regeneration dynamics
